Early Observations of an Anomalous Signal at the GC

First noted as a feature in the Galactic Center region by Goodenough & Hooper (2009)

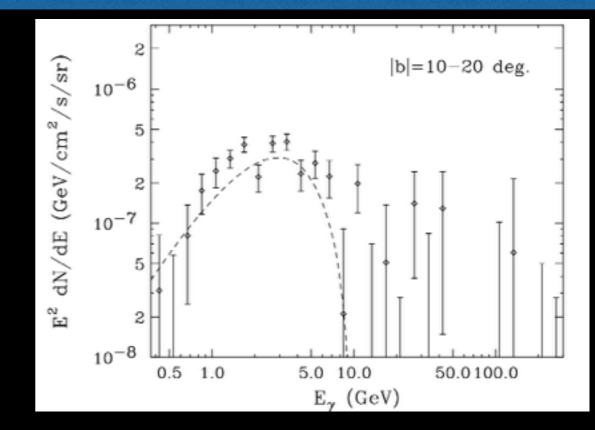

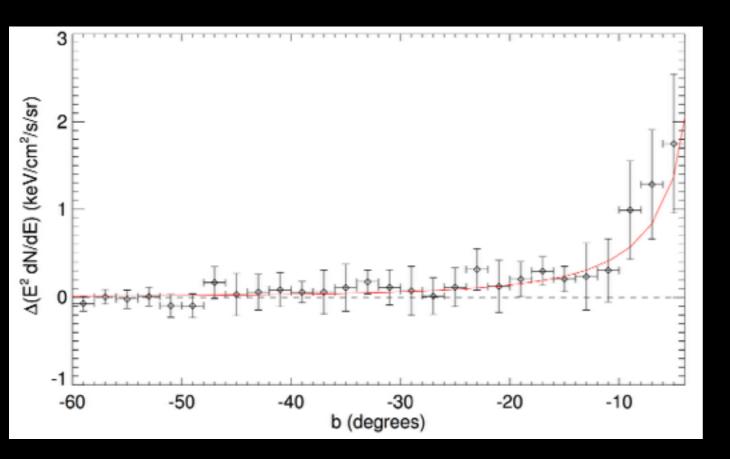

Millisecond Pulsars

10

Early Observations of an Anomalous Signal at the GC

Work by Hooper & Slatyer found this signal in a greatly expanded range, out to at least 10 degrees from the GC

This disfavors the pulsar interpretation. A large population of MSPs 10 degrees from the GC should be observable by Fermi

Three Objectives

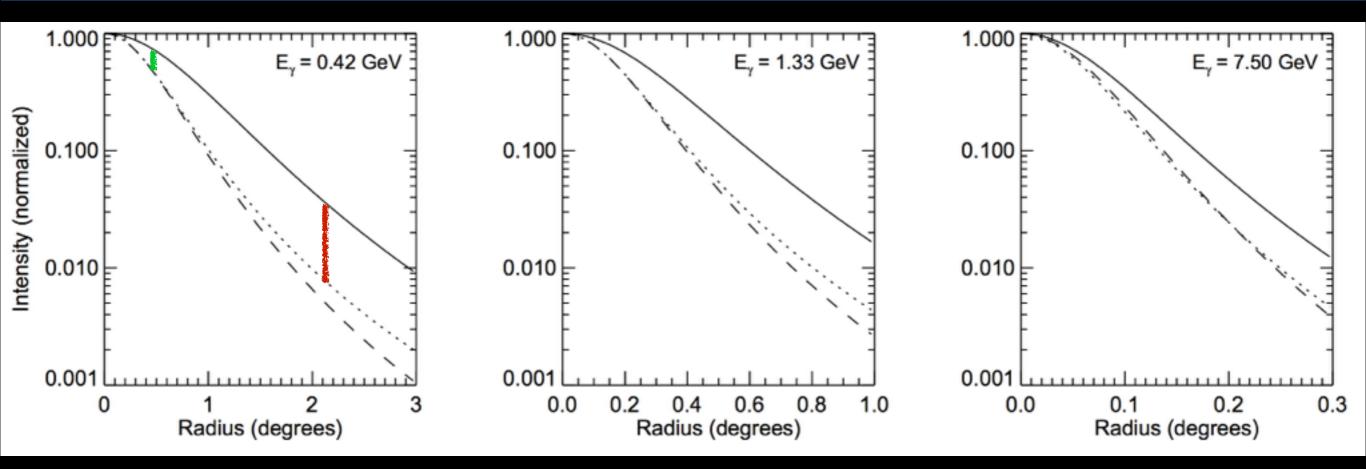

1.) Produce a significantly enhanced version of the Fermi dataset, using only photons with the best directional reconstruction

2.) Test the compatibility of the excess in the Galactic Center and Inner Galaxy

3.) Produce multiple tests of the dark matter interpretation of the data - concentrating on tests which can differentiate a dark matter or pulsar signal

http://chasm.uchicago.edu/paper.pdf

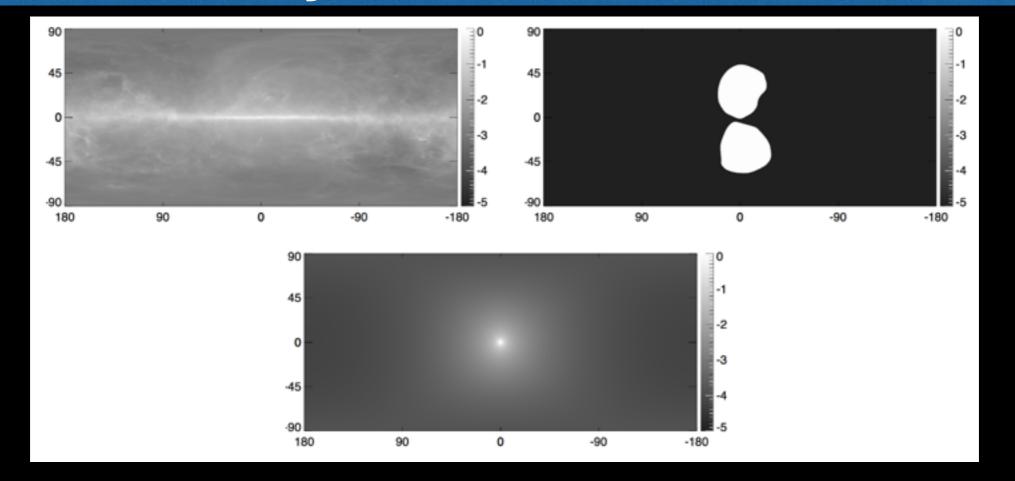

CTBCORE QUALITY CUTS

1.) Each photon observed by the Fermi-LAT has a different uncertainty in the directional reconstruction

2.) The Pass 7 analysis includes a parameter, CTBCORE, which indicates how well each individual photon was measured

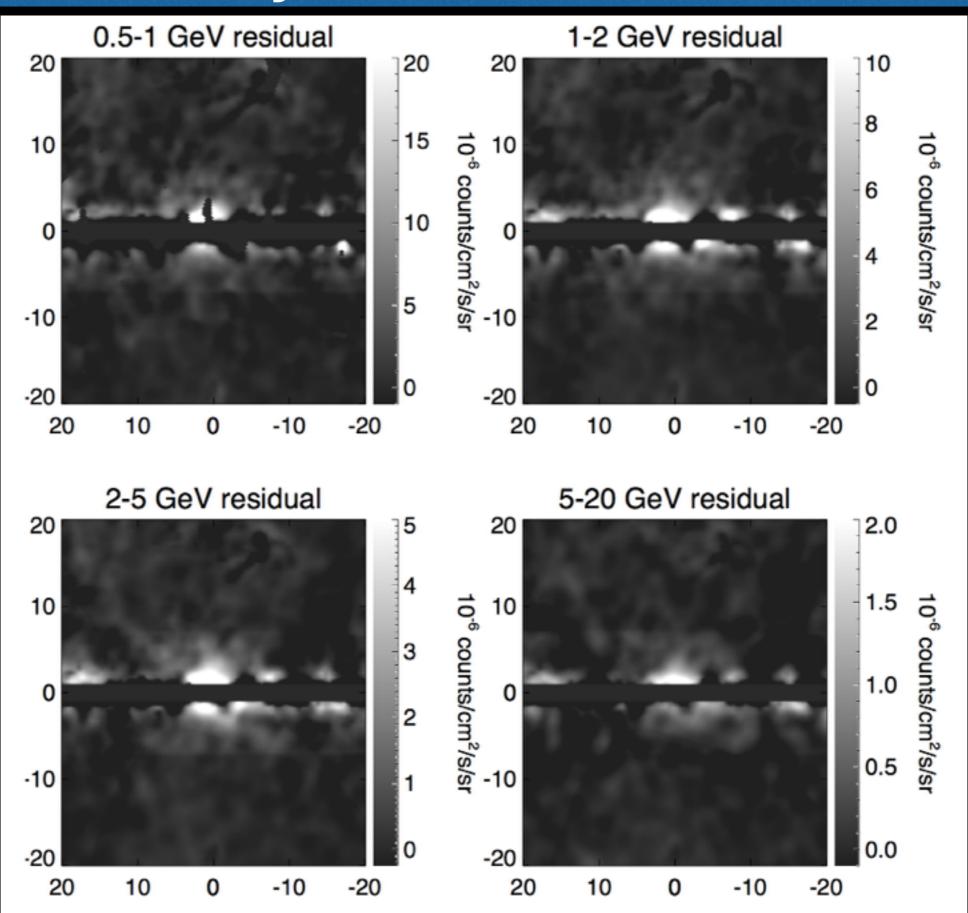

3.) We select only the 50% of photons with the best CTBCORE values, this not only improves the overall PSF, but greatly diminishes the non-Gaussian tails

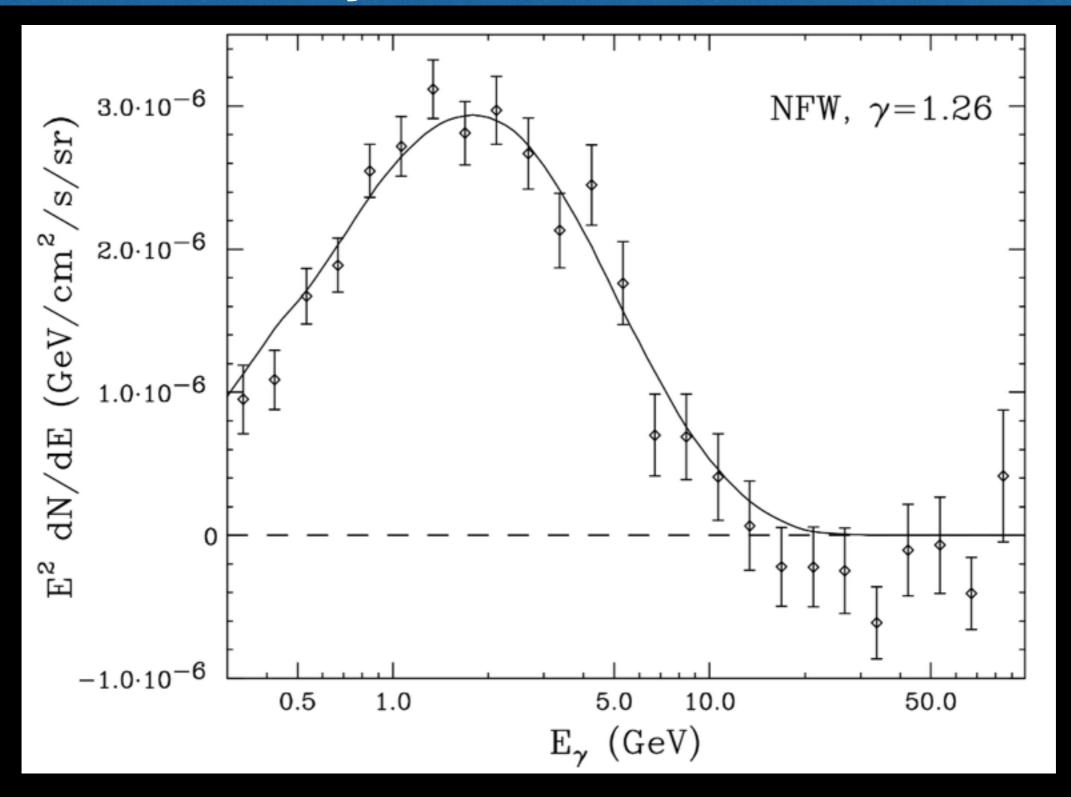

1.) Mask $|b| < 1^{\circ}$, and a 2° radius around all 1FGL sources

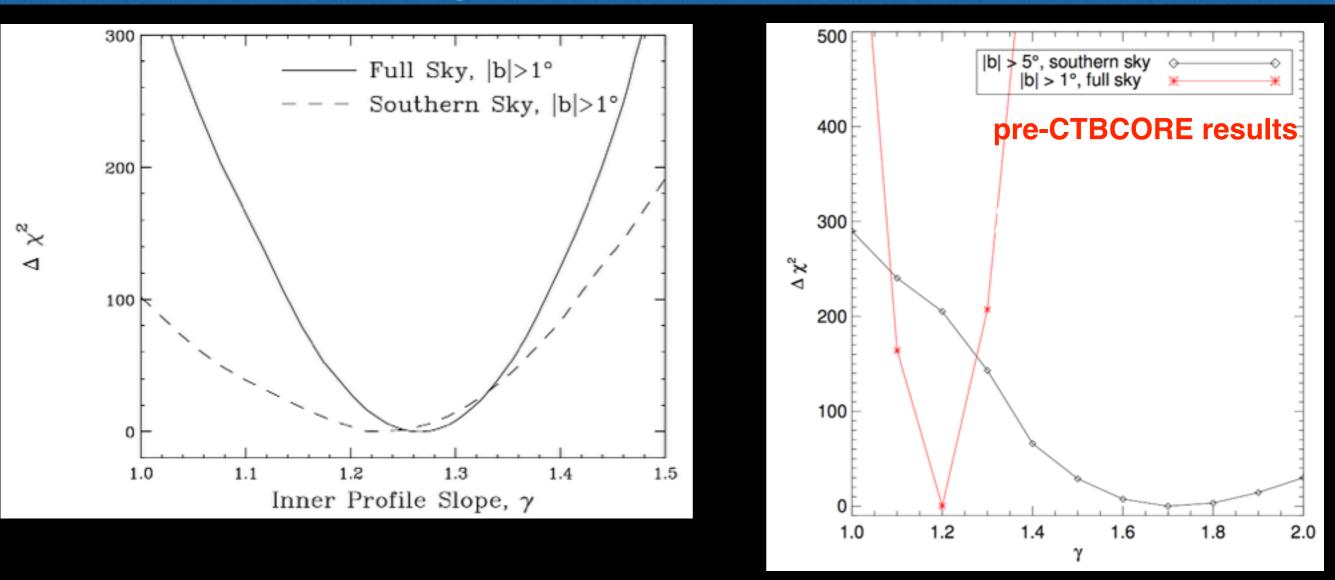

2.) Employ models for the diffuse emission, isotropic emission, Fermi bubbles, and a dark matter component

3.) Allow the normalization of each component to float in 25 different energy bins, from 300 MeV - 100 GeV

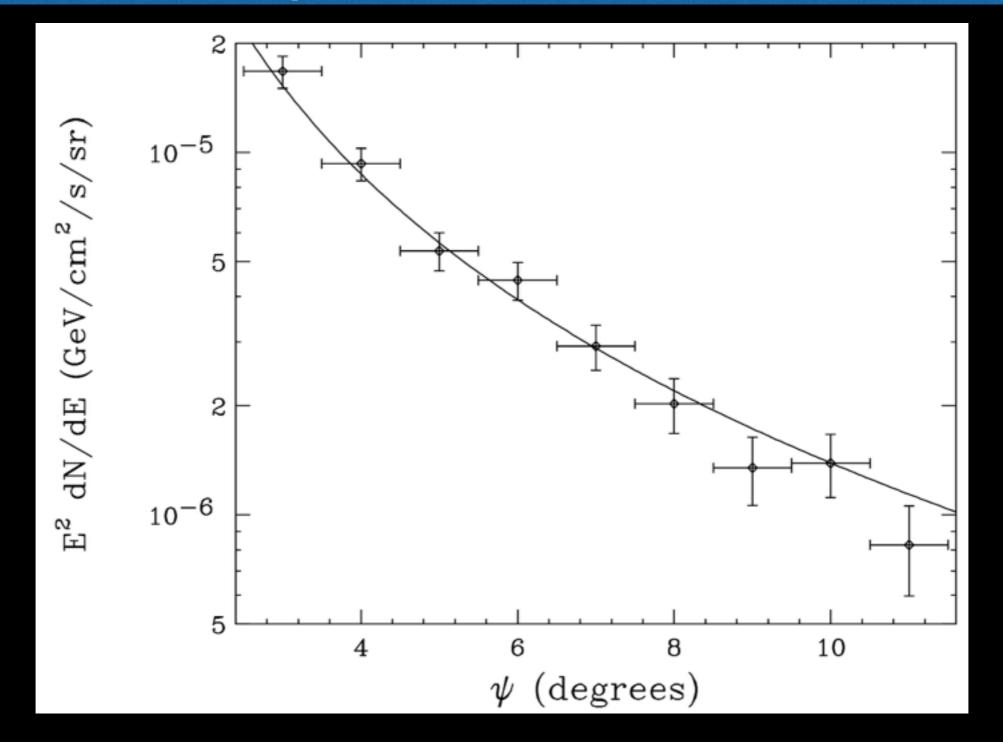

The DM template naturally picks up the following spectral shape - the spectral shape is not forced into the template in any way

The profile slope of the excess is best fit by a generalized NFW with γ =1.26. The north/south and latitude cut asymmetries have been eliminated when using the higher quality, CTBCORE data set.

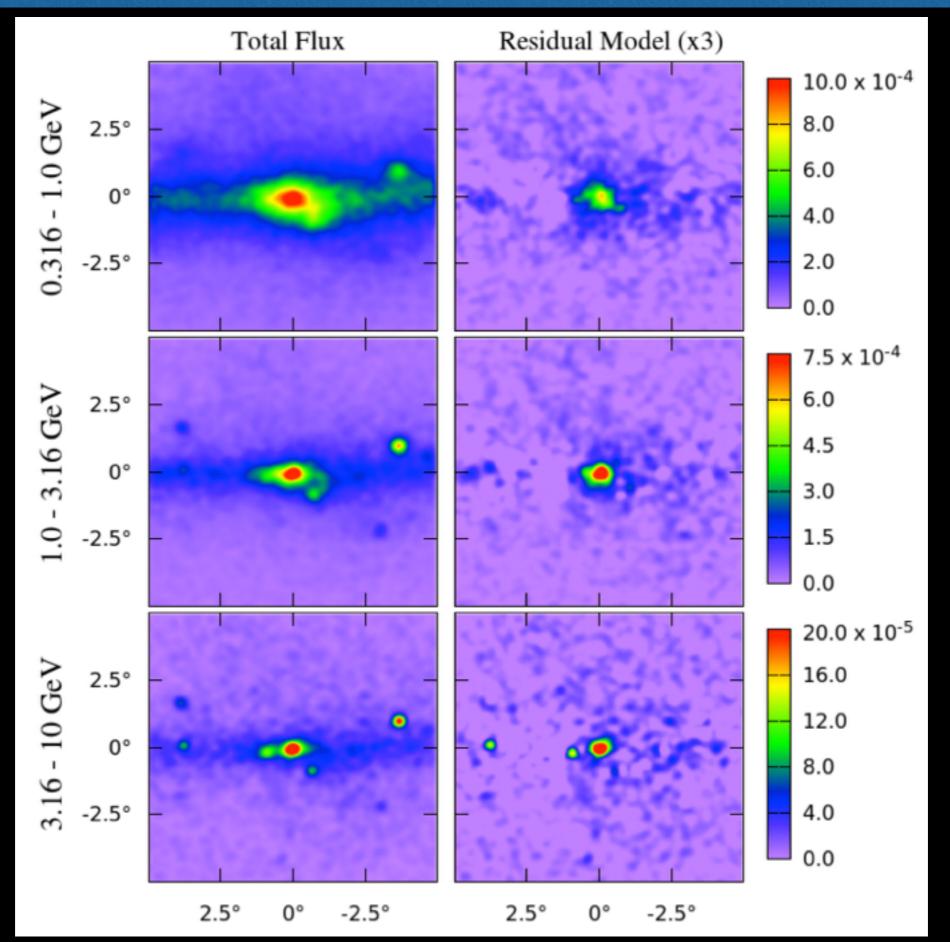

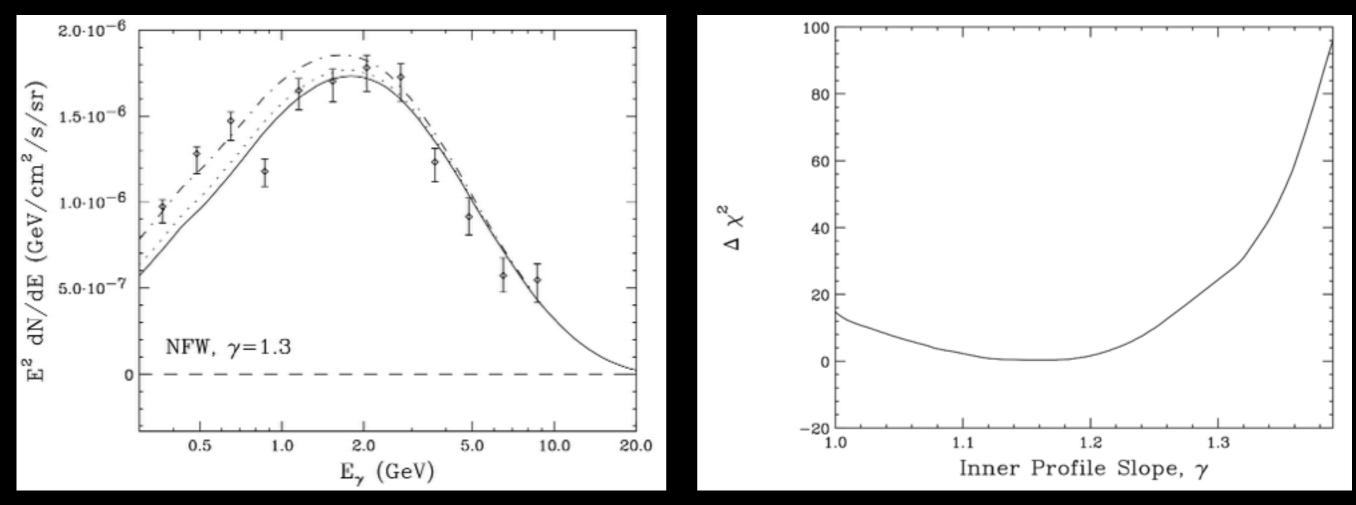

The morphology of the excess is resilient when each individual 1° ring is allowed to float independently. It becomes slightly steeper (γ =1.4), probably due to oversubtraction of the diffuse component at high latitudes

1.) Instead model the inner $||| < 5^{\circ}$, $|b| < 5^{\circ}$

2.) Must include all point sources in the model - along with models for the diffuse emission, isotropic emission, 20cm map

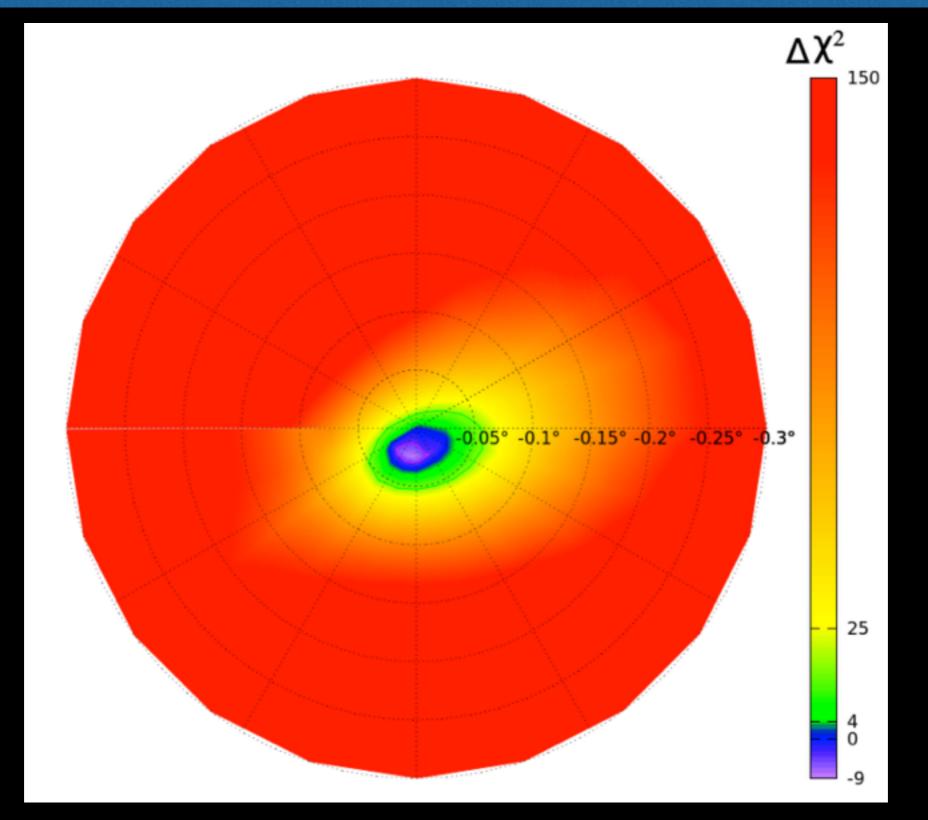

3.) In order to obtain the best fitting model, we allow the normalizations and spectra of multiple sources to vary, using the Fermi tool *gtlike* (and the MINUIT algorithm) to determine the best model for each component

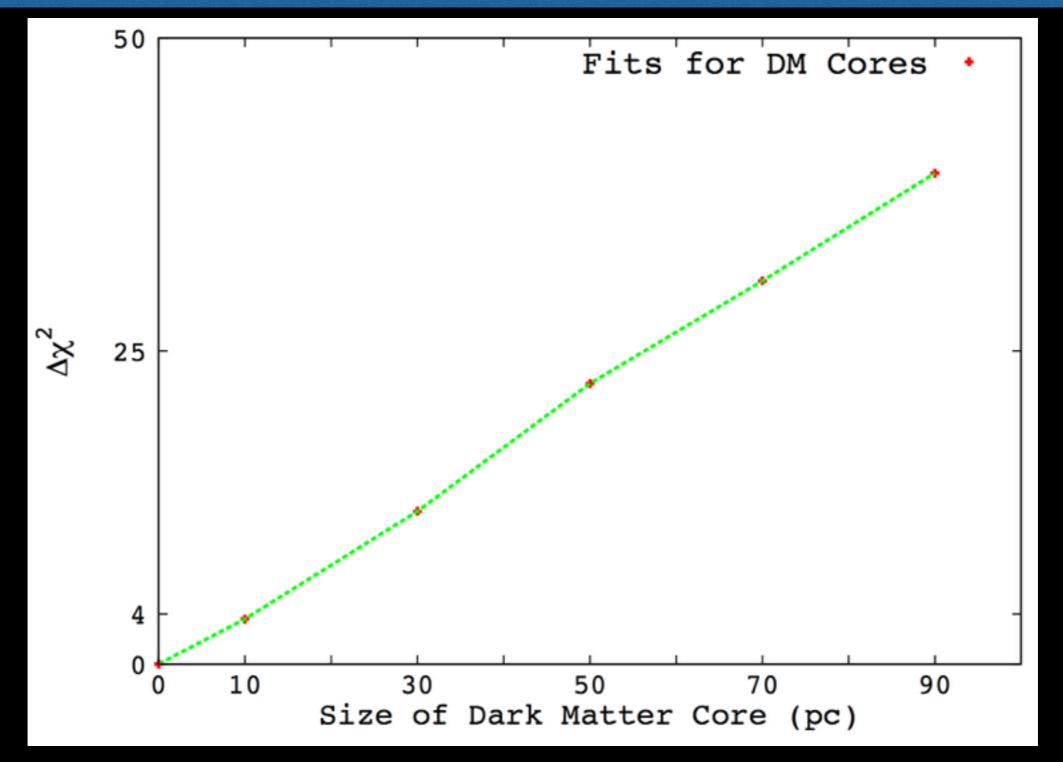

1.) The spectrum of the residual looks very similar to the spectrum of the Inner Galaxy analysis.

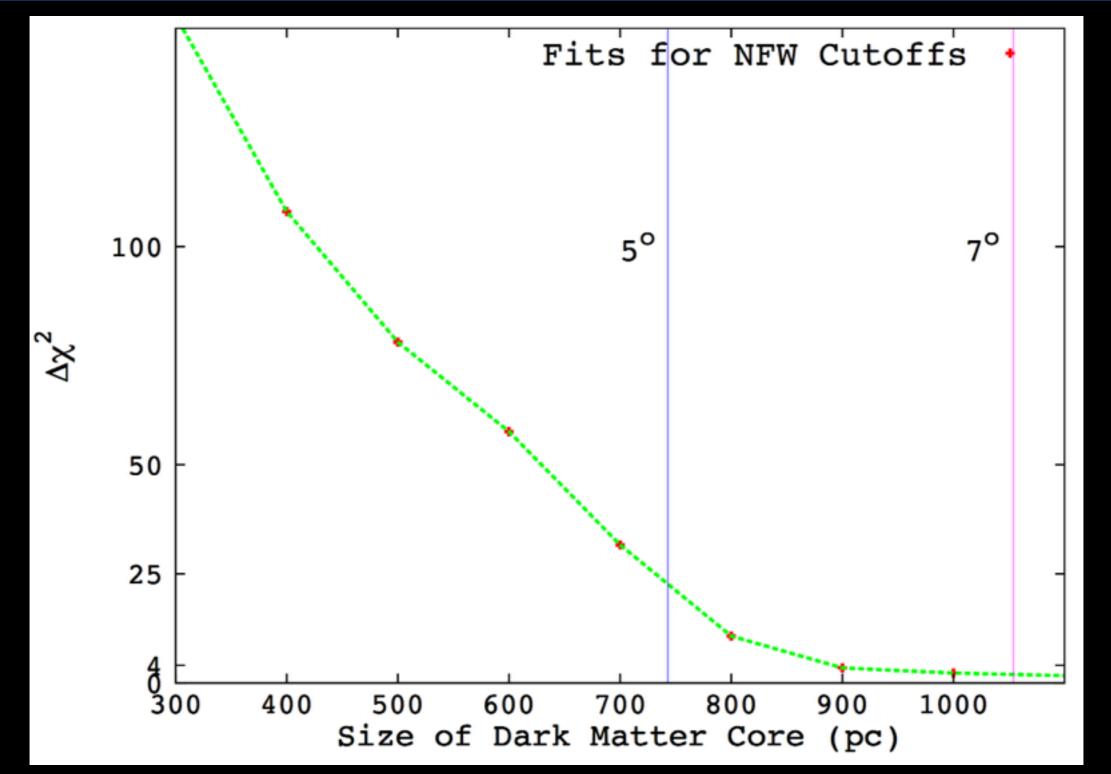

2.) The slope of the NFW profile looks to be less peaked very close to the GC (γ =1.17) — this is not at odds with simulations.

The excess is remarkably centered on the position of Sgr A*

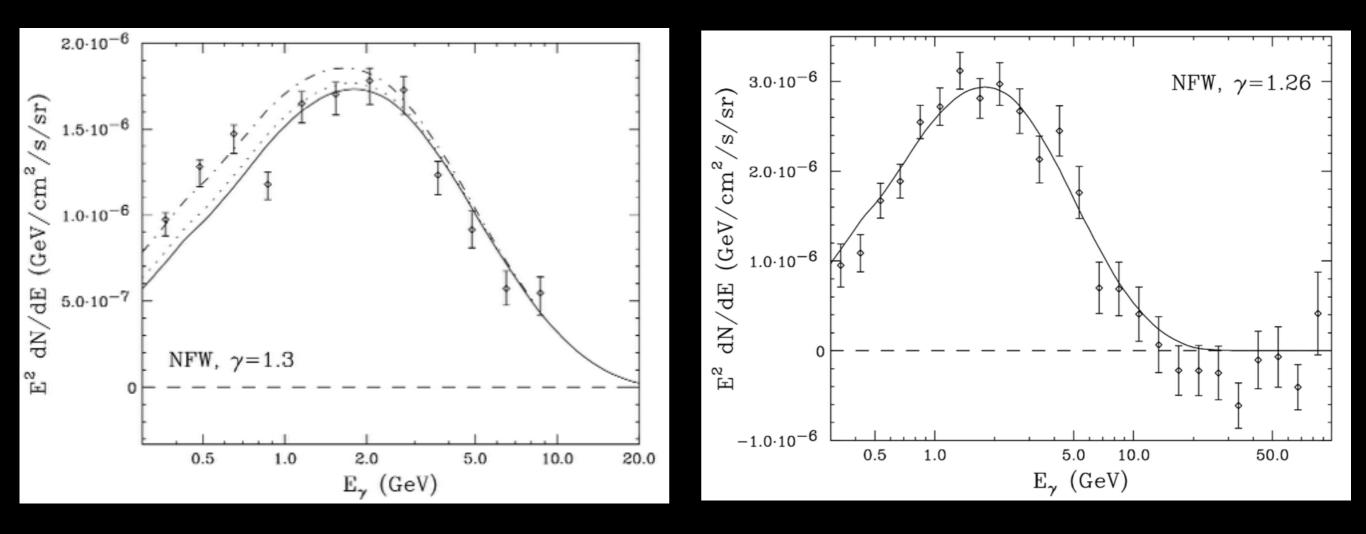

The morphology of this excess does not appear to have a core, even a core of only ~15 pc can be rejected at more than 2σ

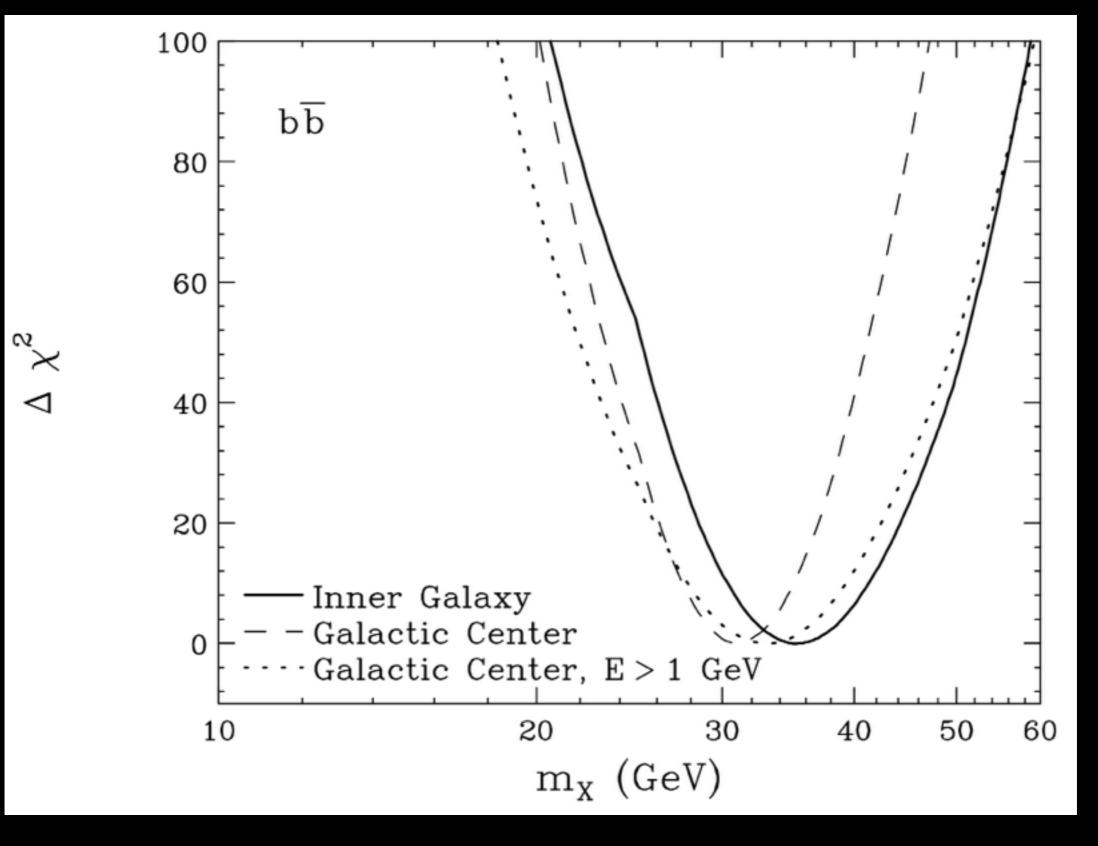

The dark matter model can also be found out to at least 800 pc from the GC (where the simulation cuts off). We have isolated a steeply falling morphology over nearly than two orders of magnitude in GC distance.

The Similar Spectrum of the Excesses

With two different, independent analysis techniques —- and using photons primarily from different regions of the sky, the spectra of these excesses looks almost identical.

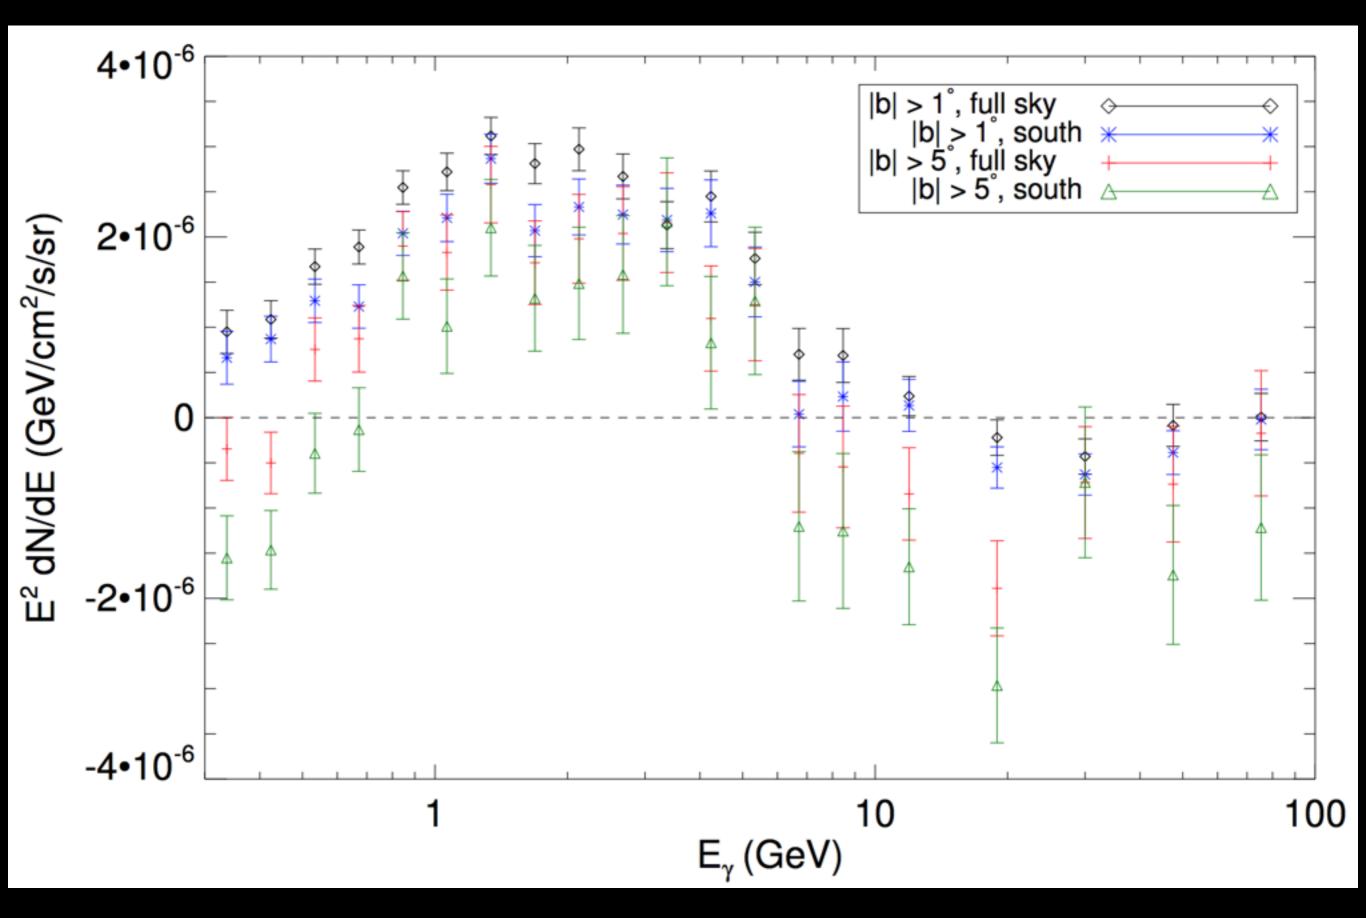

The Similar Spectrum of the Excesses

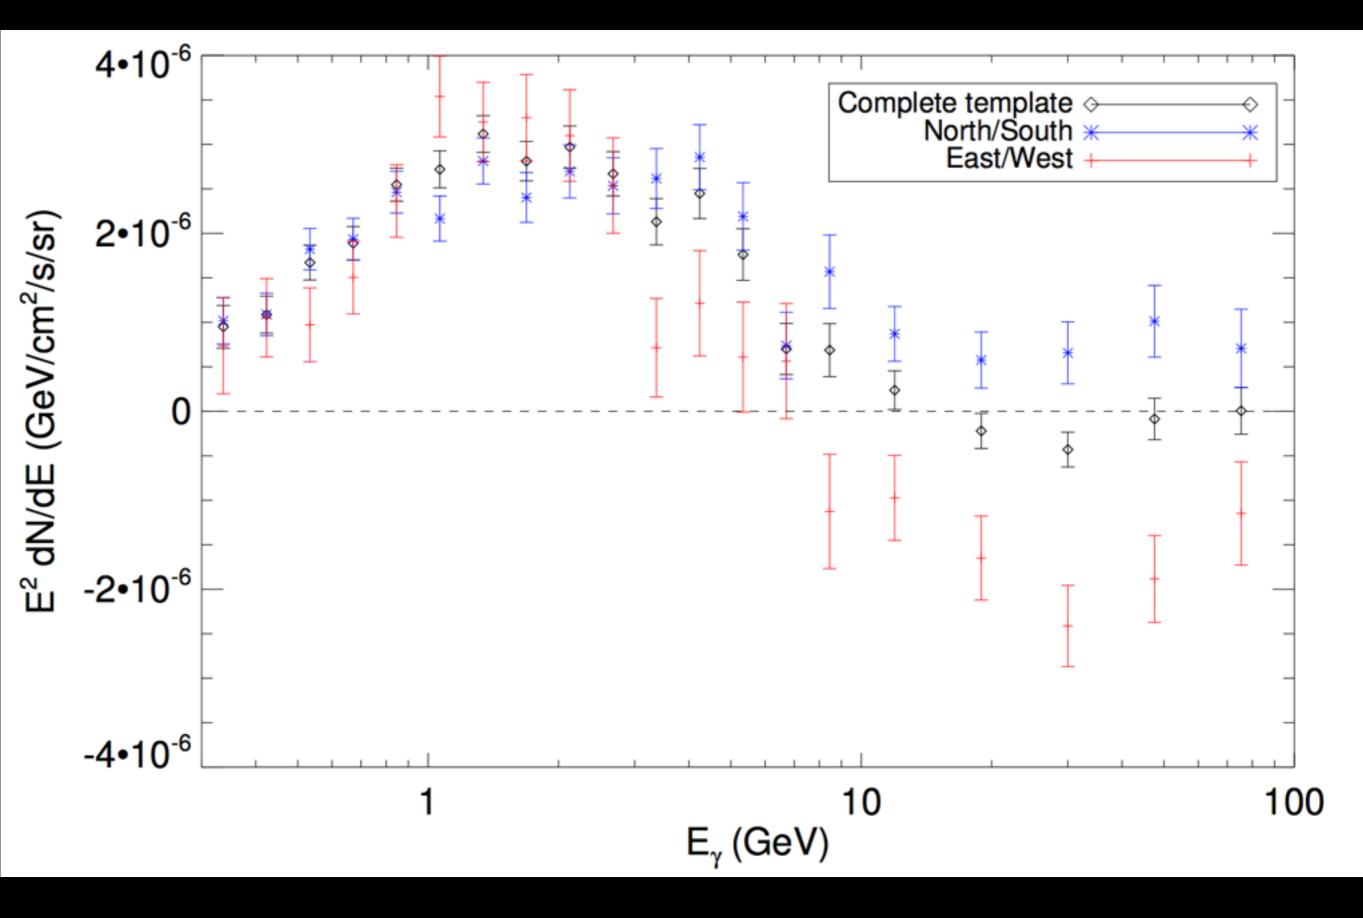

And it looks a lot like dark matter...

Extra Slides

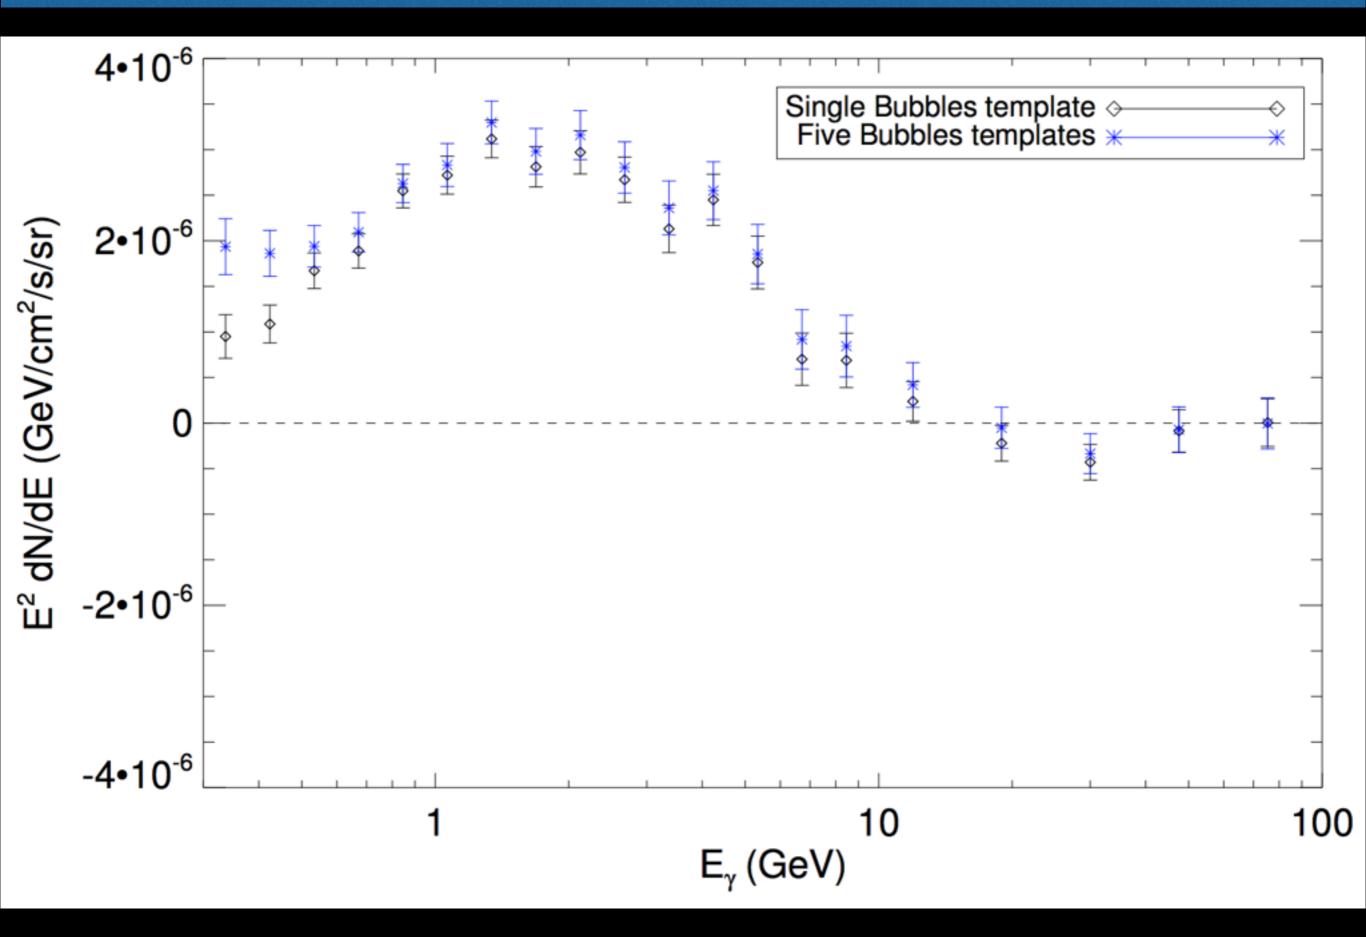

Wait, Some of the Same Photons are in Each Sample?

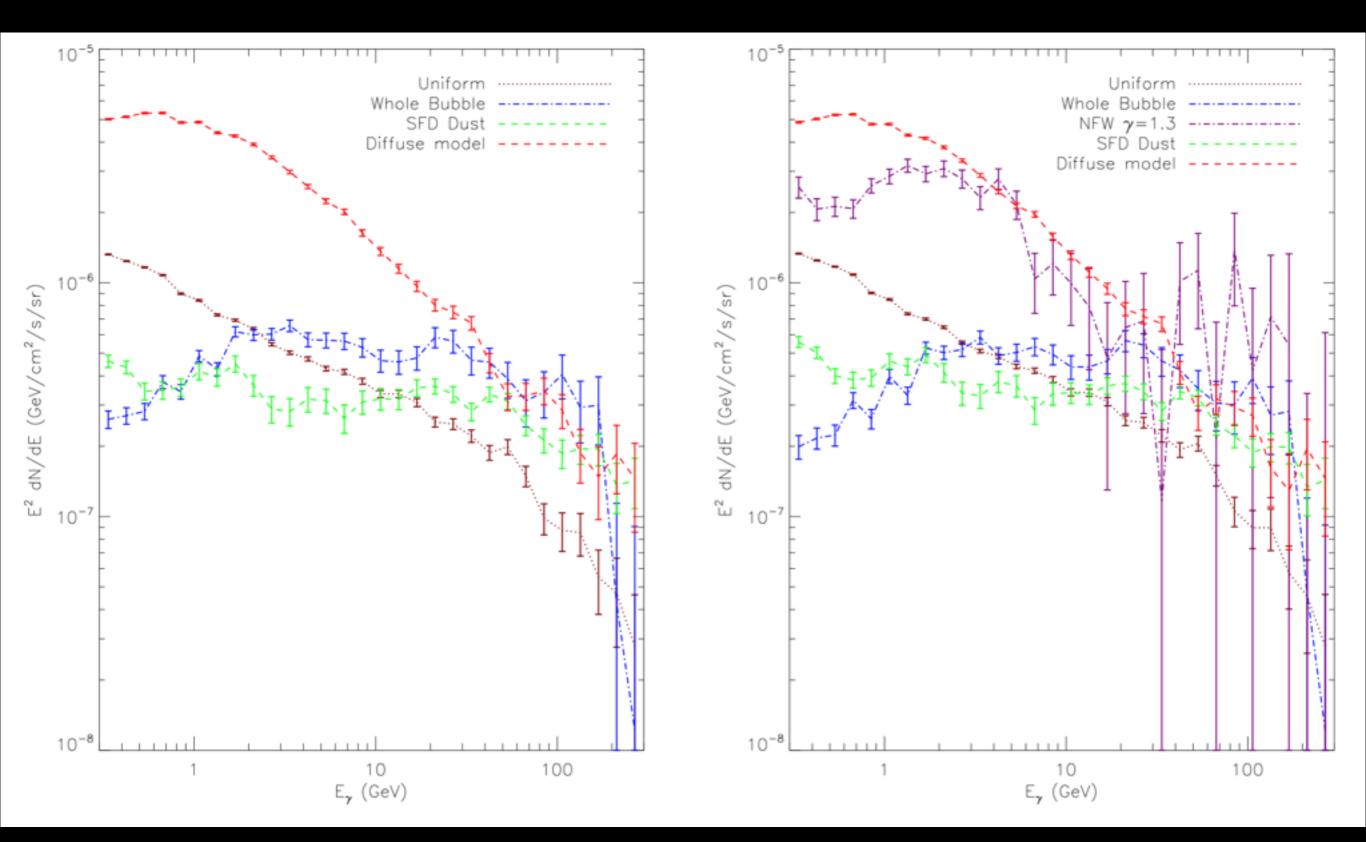

Maybe it's just part of the Bubbles?

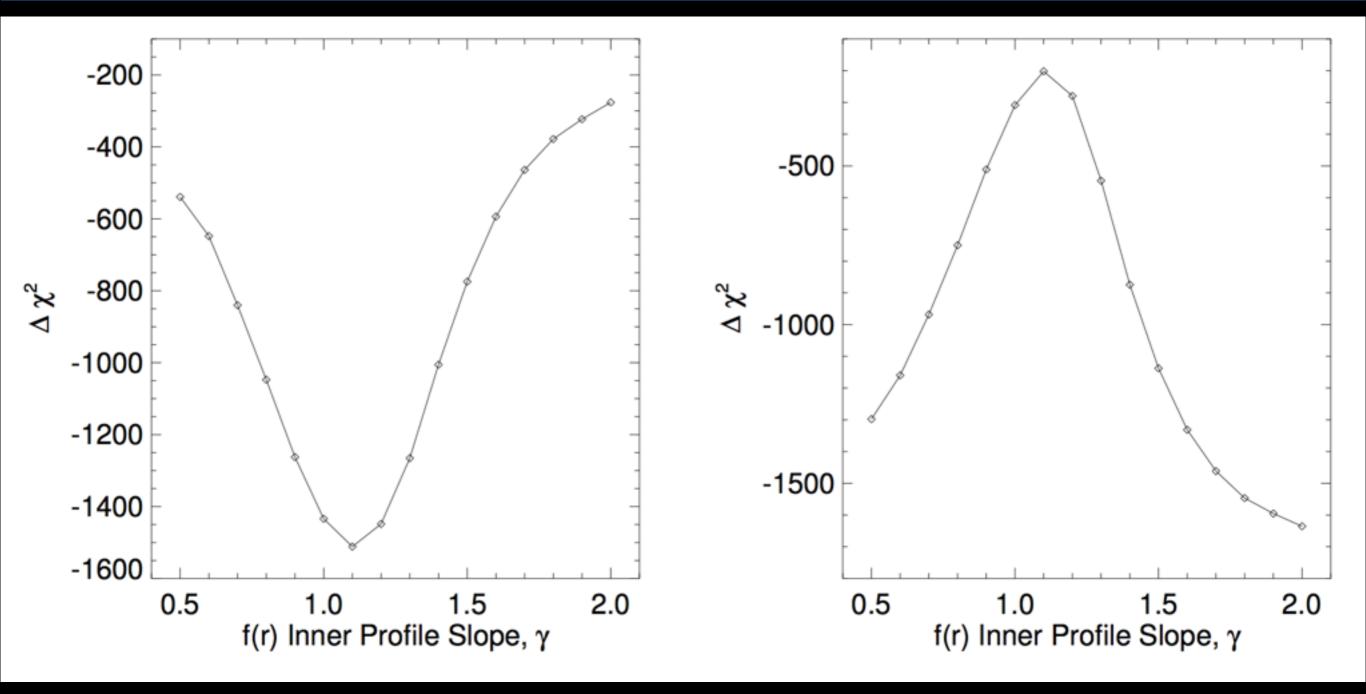

Maybe the Bubbles Have A Spectral Variation?

Does it Correlate with Gas?

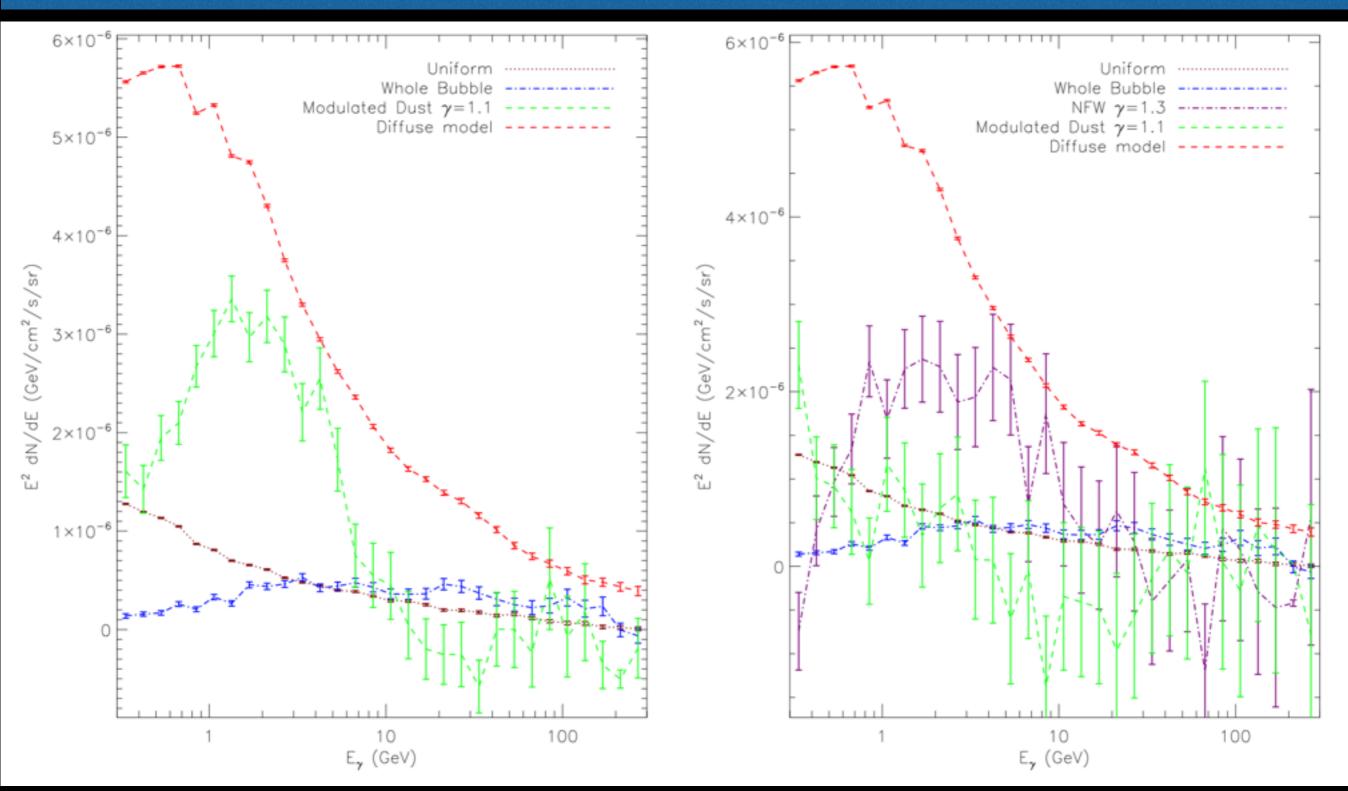

Does it Correlate with Gas?

Even more generically, you can add an f(r) a r^(-gamma) profile for the SFD template, this is highly preferred in the model with no dark matter (left), but the dark matter template is still highly preferred even when gamma can float freely (right)

Does it Correlate with Gas?

With the best fit modulated SFD map, the dark matter fit is still highly preferred

Maybe the Models of the Diffuse Emission in the GC are Wrong
